## Investigating How Programming Design Effects Real-Time Performance

### A Simulation of A Flight Control System

David Wee Ming Junn

TP062496

#### Abstract

This paper aims to explore the impact of programming design on the performance of flight management systems. The study includes the creation of a simulation of the system's core components - sensors, actuators, and the flight control system - with an explanation of the implementation and workflow. The systems mainly communicate with RabbitMQ tool, allowing data to be transferred from distinct thread to thread. The developer then analyzes and evaluates the simulation's performance based on different programming designs, utilizing benchmarks and JDK Mission Control software. For results that have little difference in performance, the sample size is expanded two folds or more. Additionally, a literature review is also conducted, to get a further in-depth understanding on real-time systems, issues of latency and solutions to measure performance of a software system. Overall, this paper demonstrates the methodology and performance outcomes resulting from the programming changes.

#### 1.0 Introduction

According to TheHealthyJournal, roughly 100,000 flights take off and land every day all over the globe. Say an average length of a flight is two hours; that would mean that six million people fly somewhere every day. (TheHealthyJournal, n.d.) It was something that was once deemed impossible, yet it continued to grow and became a part of everyone's lives. But of course, soaring through the skies is no easy feat, tallying up to 229 fatalities from 12 fatal accidents in just 2022. (Learmount, 2023) Which is why passenger airplanes are required by law to have a flight management system.

A flight management system is a real-time systems that manages and coordinates the sensory part of the airplane which measures important attributes such as the altitude, cabin pressure and airplane speed, with the actuator part of airplanes which manages the plane by making a rotary or linear motion based on the stimuli input, such as the wing flaps, engine and cabin pressurization system. Or in a simple term, the flight management system is a virtual pilot that gets the data from the sensors, decide, and pass off those decision to the actuator systems. However, there is a catch,

the system is considered as half of a hard real-time and half of a soft real-time. This is because the flight management system has both hard and soft real-time components, depending on the specific data involved and the consequences it brings if time constraints are not obeyed. For example, the altitude is considered as a data of high value, if the altitude is too low and it was subjected to delay, unable to meet the deadline, a collision might occur just because the wing flaps did not receive the instruction to move the airplane up in time, devastating untold lives. As a result, a developer is tasked to investigate the affect of programming design towards real-time performance. The main reason for this investigation is to explore different techniques and strategies that can be used to reduce latency within the flight management system to improve the performance of a passenger airliner flight management system.

The developer is required to create a simulation of a flight management system and analyse the speed, efficiency and reliability of the system in addition to documenting any modification that helped in improving performance. Moreover, the

developer is expected to utilise a messaging system to facilitate communication between various components of the flight control system, sensor systems and actuator systems. All in all, this report exemplifies the developers attempts in simulating a flight management system, refining the performance of the system and detecting performance obstacles.

## 2.0 Research Background/Literature Review

### 2.1 What is latency?

(Bakar & Jamal, 2020) offers a comparison of studies and solutions related to latency issues in the Internet of Things (IoT) resource discovery. The study defines latency as one-way delay, which is the amount of time for data to move from one point to another. According to the study, hardware-produced latency is relatively constant, while software-produced latency varies greatly and is therefore difficult to measure directly.

The study emphasizes the importance of IoT latency solutions in enabling latency-sensitive applications to operate as planned. By filtering and evaluating latency issues, the IoT can be tailored to ensure that critical IoT latency requirements are met, as latency cannot be completely eliminated. The study also introduces methods for measuring latency, such as using timestamping packets to determine delays accurately without additional overhead. However, the study raises questions that need to be addressed, such as "Why is it so important to reduce latency?" "Why can't latency-sensitive applications operate as expected because of latency?" and "How can an IoT be tailored to meet latency requirements?"

### 2.2 Hard & Soft Real Time System

The term "real-time system" refers to any information processing system with hardware and software components that perform real-time application functions and can respond to events within predictable

and specific time constraints. (Intel, n.d.) Real Time system is categorized into hard and soft. Hard real time system(HRTS) has extremely strict and high standards on time constraints, as failure to meet deadline results in serious consequences. (GeeksForGeeks, n.d.) On the contrary, soft real time system (SRTS) offers some leeway in terms of deadlines. This is because although the operation or data starts to degrade as the deadline passes, no major repercussion would occur as a result of it.

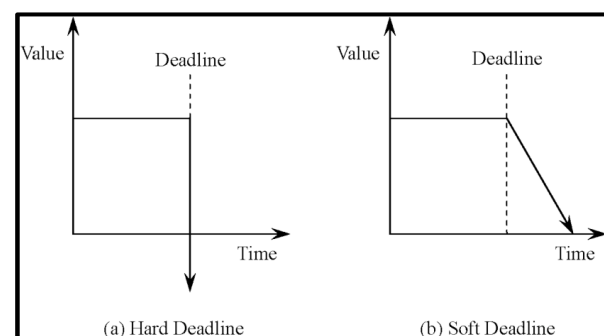

Figure 1: Hard vs Soft Deadline

### 2.3 Understanding the effect of latency

(Claypool, 2005) researches the effect of latency on user performance in Real-Time Strategy games. The study conducts experiments with human participants playing RTS games with varying levels of network latency. With that, the study presents evidences that latency has a significant effect on user performance and user experience in the games conducted, with the user with high latency leading to slower user response times and decreased user performance. However, it is important to note that events that happen are consistent among all users, all users witness the same events unfolding with the high latency user seeing the event a little later, meaning latency does not stop data from being transferred, it just delays it. However, with the latency, it is noted that a latency of 500ms or more had a significant impact on the users' performance in RTS games. Thus, to relate it to this report, if latency is low and at an acceptable range, the flight

management system will be able to run smoothly. If latency is high, the flight management system will not be able to react properly according to the real-time stimuli from sensors.

## 2.4 Performance Evaluation with Benchmarking

There exist various methods to evaluate and gauge the performance of a system. Among these techniques, benchmarking holds significant importance in system development, a process of measuring products, services and processes. (ASQ, n.d.) However, selecting the appropriate benchmarking tool can be a challenging task. This is because the developer uses threads that are not expected to stop and RabbitMQ for the threads to communicate with each other. Therefore, in addition to testing the performance of the interaction between the threads and the processor, the developer needs to test the performance of said communication. But of course, due to the nature of the code, the thought of applying java micro-benchmarking(JMH) might be out of the question. This is because to apply JMH, specific rules need to be followed in regards to the annotations. Unfortunately, the starting point is in one thread while the stopping point is in another thread, making it difficult to use JMH. With that in mind, it is worth mentioning that benchmarking primarily provides a standardized and reproducible way to compare performance across different systems or components. Therefore, it should be considered to utilize performance monitoring tool instead, and compare the results manually. Although it may be less standardized than benchmarking, it is not inferior in terms of accuracy.

## 2.5 How to reduce Latency

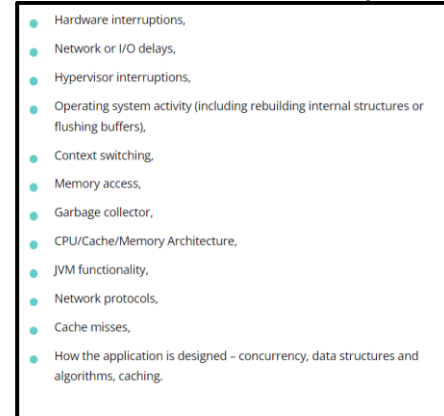

Figure 2: Reasons for Latency (StratoFlow, n.d.)

According to (StratoFlow, n.d.), the factors listed in Figure 2 are the main causes of delays in applications or systems. Moreover, solutions to decrease latency include...

1. Choosing the correct programming language
2. Remember about memory and garbage collection.
3. Provide a system buffer.
4. Pay attention to caching.
5. Keep your code simple.

Among these solutions, solution 2 and 5 deserve a closer attention. In Java, garbage collection is an automatic process, the programmer does not need to explicitly mark objects to be deleted. (Nayak, 2021) However, it's worth noting that operations that are running but does nothing are essentially garbage. These garbage are not marked by the garbage collector as it is assumed to be doing "something". Therefore, it is the job of the developer to ensure such operations cease to run when they finish their tasks. For example, a thread awaiting messages that are never coming. Next in line, the code should be kept simple, avoiding any unnecessary actions. In other words, the code should be optimized in a way that finishes a requirement with the least of lines.

## 3.0 Methodology

### 3.1 Overview of Simulation

The purpose of this study is to analyse the performance of a simulated flight management system and search for ways to increase the performance of the system. As

instructed by the case study, the flight management system is categorized into three sections, the sensory systems, flight control system and actuator systems as shown in Figure 3.

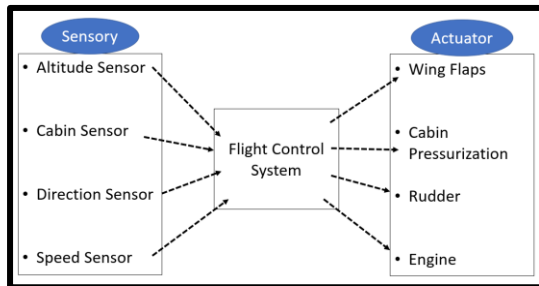

Figure 3: Visualization of Simulation's workflow

The simulation starts with the sensory systems generating inputs. The inputs are then sent to flight control system via RabbitMQ. When the flight control system receives the input, it analyses the data and subsequently arrives at a decision and sends the instruction to the intended actuator systems with RabbitMQ. In the end, the actuator systems receive and perform accordance to the acquired instruction.

### 3.2 Implementation

The entire code of file necessary for understanding the flow of the simulation will be available in the appendix. This section is merely to show the workflow of the simulation. Therefore, instead of the entire sensory systems, the entire flight control systems, the entire actuator systems, snippets of each systems will be shown and explained in details.

```

ScheduledExecutorService Sensors = Executors.newScheduledThreadPool(4);
Sensors.scheduleAtFixedRate(new
Altitude_Sensor(currentAltitude), 0, 1500, TimeUnit.MILLISECONDS);
Sensors.scheduleAtFixedRate(new
Cabin_Sensor(currentPressure, startLossOfCabinPressure), 0, 1500, TimeUnit.MILLISECONDS);
Sensors.scheduleAtFixedRate(new
Direction_Sensor(currentDirection), 0, 1500, TimeUnit.MILLISECONDS);
Sensors.scheduleAtFixedRate(new
Speed_Sensor(currentSpeed), 0, 1500, TimeUnit.MILLISECONDS);
  
```

Figure 4: Thread Execution

Figure 4 shows a snippet of the Main file, where threads of the sensory system is activated. Since each sensory is distinct from each other, the simulation has 4 threads for sensory system, 4 threads for actuator system and 2 threads for flight control system. As indicated, the sensory threads are executed once every 1500

milliseconds for reasons that will be explained below.

```

public void run() {
    Thread.currentThread().setName("Altitude_Sensor");
    double pri_altitude = currentAltitude.doubleValue();
    changeInAltitude = rand.ints(-500, 500)
        .findFirst()
        .getAsInt();
    currentAltitude.getAndAdd((int) changeInAltitude);

    DecimalFormat df = new DecimalFormat("0.00");
    String strCurrentAltitude = df.format(currentAltitude);
    String strChangeInAltitude = df.format(changeInAltitude);

    System.out.println(Thread.currentThread().getName() + "
    try{
        Altitude_Sensor.sendAltitude(strCurrentAltitude);
    }catch(Exception e){
  
```

Figure 5: Modification of Altitude

Figure 5 is a snippet from the altitude sensor file. It mainly shows what the sensor does when it is executed. Since the simulation is primarily meant to simulate the reaction of the actuators depending on the stimuli, the sensors generate random measurements. In other words, the actions of the actuators are based off the sensors and not the other way round. The sensor works by first generating a random altitude between 500ft to -500ft and adding it to the current altitude. The current altitude is then sent to the flight control system with the function "sendAltitude()".

```

public static void sendAltitude(String currentAltitude) {
    String ex = "SensoryExchange";
    String key = "Altitude";

    //1.create connection
    ConnectionFactory cf = new ConnectionFactory();

    //2.use Factory to create a connection
    try(Connection con = cf.newConnection()){

        //3.create a channel using the connection
        Channel chan = con.createChannel();

        //4.Declare a queue or exchange
        chan.queueDeclare(qName, false, false, false, null);
        chan.exchangeDeclare(ex, "direct"); //type direct

        //5.send/publish message
        chan.basicPublish(ex, key, null, currentAltitude.getBytes());
    }
  
```

Figure 6: Sending of Altitude

Before sending the data to flight control system, a connection to the flight control system's receiver must be made. The procedures are as of below...

1. Create an instance of 'ConnectionFactory'

✚ Connection Factory is a class needed to help create a connection to a message broker.

2. Establish a connection to the message broker.

✚ A message broker is software that enables applications, systems, and services to communicate with each other and exchange information. (IBM, n.d.)

3. Create a new channel using the connection.

✚ Channel is a virtual connection inside a connection and publishing or consuming a message from queue will happen over a channel. (Tutlane, n.d.)

4. Declare an exchange of direct type.

✚ The direct exchange will route the message to a specific queue based on exchange key which is "SensoryExchange".

5. The message is published to the exchange.

✚ In addition to the routing key, a name is assigned to this message. Allowing only the intended receiver with the same key and name to access this message.

```
public static void getAltitude(LinkedBlockingQueue<String>
String ex = "SensoryExchange";
String key = "Altitude";

ConnectionFactory cf = new ConnectionFactory();
Connection con = cf.newConnection();
Channel chan = con.createChannel();

chan.exchangeDeclare(ex, "direct"); //fanout

//get queue
String qName = chan.queueDeclare().getQueue();

//connect/bind queue with exchange
chan.queueBind(qName, ex, key); //fanout: key -> ""

//thread name
String threadName = Thread.currentThread().getName();

chan.basicConsume(qName, (x, msg) -> {
String m = new String(msg.getBody(), "UTF-8");
System.out.println(threadName + " ## Received Altitude: " + m);
try {
AltitudeQueue.put(m);
} catch (Exception ex1) {}
}, x -> {});
}
```

Figure 7: Flight Control System Altitude Receiver

Since data is sent from the sensory system, the flight control system must have receiver to receive these data. The procedure of

receiving the data excluding connection creation is as follow...

1. Declare a new message queue on the channel and get its name.
2. Binds the message queue to the exchange using the routing key, name of queue, and name of message.
3. Register a consumer to receive messages from the message queue. The received messages are then processed by the lambda expression, which then retrieves the message.

When the message is received, it is put into a linked blocking queue named AltitudeQueue.

```
String speed = null;
while(!AltitudeQueue.isEmpty()){
altitude = AltitudeQueue.take();
}
while(!CabinPressureQueue.isEmpty()){
pressure = CabinPressureQueue.take();
}
while(!DirectionQueue.isEmpty()){
direction = DirectionQueue.take();
}
while(!SpeedQueue.isEmpty()){
speed = SpeedQueue.take();
}

if ((altitude != null) && (StatusLossOfCabinPressure.get()
//15000 is starting altitude
//altitude must stay between 14500 - 15500
if(Double.parseDouble(altitude) < 14500){
System.out.println(Thread.currentThread().getName
sendToActuatorDirect(WingFlapsUpInstruction,1);
}else if(Double.parseDouble(altitude) > 15500){
System.out.println(Thread.currentThread().getName
sendToActuatorDirect(WingFlapsDownInstruction,1);
}
}
```

Figure 8: Flight Control System Decision Making for Altitude

Just like altitude sensor, the other three sensory system does the same. Hence, every time the thread representing the flight control system activates, it clears the queues until the very last or recent measurement. If altitude is below or above the intended rate, the flight control system sends an instruction towards the wing flaps. The method of sending the instruction to the actuator system is no different from the altitude sensor sending the measurement to the flight control system. The only difference in this transaction is the exchange key and the name of the message.

```

public static void getInstruction() throws IOException {
    String ex = "ActuatorDirectExchange";
    String key = "WingFlaps";

    ConnectionFactory cf = new ConnectionFactory();
    Connection con = cf.newConnection();
    Channel chan = con.createChannel();

    chan.exchangeDeclare(ex, "direct"); //fanout

    //get queue
    String qName = chan.queueDeclare().getQueue();

    //connect/bind queue with exchange
    chan.queueBind(qName, ex, key); //fanout: key -> "

    String threadName = Thread.currentThread().getName();

    chan.basicConsume(qName, (x, msg) -> {
        String m = new String(msg.getBody(), "UTF-8");
        System.out.println(threadName + " -> WingFlaps: " + m);
        currentAltitude.set(15000);
    }, x -> {});
}

```

Figure 9: Wing Flaps Response

When an instruction is received, the wing flaps follow the instruction and reset the altitude to its original value of 15000 feet. Although this reset may seem unorthodox, it is crucial for the simulation because the altitude sensor randomly increments and decrements the altitude, which may result in continuous indication of low altitude despite the wing flaps' constant efforts to increase altitude. For the sample output, please refer to the appendix.

### 3.3 Performance Analysis

Figure 10: Realtime Development Considerations

The performance of this system is categorized into three separate category; speed, reliability and efficiency. Before improvement can be made to the simulation, the current performance of the simulation must be measured and recorded.

#### 3.3.1 Micro-benchmarking

Micro-benchmarking is used in this simulation to evaluate the execution time of the threads. However, as previously

mentioned, benchmarking thread is difficult or is above the ability of the developer. Therefore, a separate replica of a thread is created for benchmarking. Additionally, instead of creating a replica for every threads, for the purpose of identifying obstruction and improving performance, only a replica is created on the thread that has the most operation; the flight control system.

```
org.openjdk.jmh.Main.main(args);
```

Figure 11: Code to run benchmark

```

public class BM_sendActuatorFlightControl {
    @Benchmark
    @BenchmarkMode({Mode.AverageTime}) // find t
    @Measurement(iterations = 4) // n of itera
    @OutputTimeUnit(TimeUnit.NANOSECONDS) // d
    @Warmup(iterations = 2) // literally
    @Fork(5) // Every iteration is split to a
    public boolean sendInstruction() {
        try{
            LinkedBlockingQueue<String> Altitu
            LinkedBlockingQueue<String> CabinF
            LinkedBlockingQueue<String> Direct
            LinkedBlockingQueue<String> SpeedQ
            AtomicInteger StatusLossOfCabinPre

```

Figure 12: Micro-Benchmarking Configuration in Flight Control System

1. `@BenchmarkMode({Mode.AverageTime})` notifies the Java Microbenchmark (JMH) to compute the average time taken for each benchmark execution. In other words, to get accurate measurement, the benchmark method is ran 4 times as stated in the `@Measurement`.
2. `@Measurement(iterations = 4)`. As stated, this annotation specifies the number of iterations the benchmark will be ran.
3. `@OutputTimeUnit(TimeUnit.NANOSECONDS)`. This annotation displays the results in nanoseconds. It could also be changed to another units such as seconds or milliseconds depending on the sensitivity required for the program.
4. `@Warmup(iterations = 2)`. This annotation shows that the benchmark will be executed once as

warmup. This is to minimize inaccuracy of the benchmark by warming up the java virtual machine in advance.

5. @Fork(5). According to the information given above, the program will be officially iterated 4 times and ran 5 times in separate JVM instances to help smooth out any variation in performance caused by factors such as caching, CPU scheduling and other system-level effects.

## 4.0 Results and Changes

### 4.1 First Configuration - Threads

```
14226482.162 ±(99.9%) 1464134.164 ns/op [Average]
(min, avg, max) = (12198345.067, 14226482.162, 16562624.338), stdev = 1369552.006
CI (99.9%): [12762347.998, 15690616.326] (assumes normal distribution)
```

Figure 13: Benchmarking result of Flight Control System Replica

According to Figure 13, the average time taken to complete one operation is of 14226482.162 nanoseconds. With the lowest time at 12198345.067ns and the highest time at 16562624.338ns. Additionally, the standard deviation 1369552.006 indicates that the results are somewhat varied but not excessively so.

```
while(!AltitudeQueue.isEmpty()){
    altitude = AltitudeQueue.take();
}
while(!CabinPressureQueue.isEmpty()){
    pressure = CabinPressureQueue.take();
}
while(!DirectionQueue.isEmpty()){
    direction = DirectionQueue.take();
}
while(!SpeedQueue.isEmpty()){
    speed = SpeedQueue.take();
}
```

Figure 14: Snippet to be changed (4.1)

This snippet is from flight control system that yields data from Linked Blocking Queues, attempting to get the tail data or also known as the most recent data. This snippet of code is chosen to be modified as it loops numerous times until the queues are empty.

```
Thread t1 = new Thread(Runnable) new getAltitude(AltitudeQueue, altitude));
Thread t2 = new Thread(Runnable) new getPressure(CabinPressureQueue, pressure));
Thread t3 = new Thread(Runnable) new getDirection(DirectionQueue, direction));
Thread t4 = new Thread(Runnable) new getSpeed(SpeedQueue, speed));

t1.start();
t2.start();
t3.start();
t4.start();

t1.join();
t2.join();
t3.join();
t4.join();
```

Figure 15: Utilization of threads in the snippet

Instead of sequential execution, threads can be created to run the 4 distinct data procurement snippet in concurrent or depending on the core, parallelly. Either way, the utilization of threads significantly decreases the time required to acquire these data.

```
Result "com.mycompany.FlightControl.BM_sendActuatorFlightControl.sendInstruction":
11283501.941 ±(99.9%) 993810.901 ns/op [Average]
(min, avg, max) = (9964919.900, 11283501.941, 12375478.863), stdev = 929611.334
CI (99.9%): [10289691.040, 12277312.842] (assumes normal distribution)
```

Figure 16: Result after addition of threads

According to Figure 16, the average time taken to complete one operation is of 11283501.941 nanoseconds. With the lowest time at 10289691.040ns and the highest time at 12277312.842ns. Additionally, the standard deviation 929611.334 indicates lesser fluctuation or less jitter as compared to “before”. With this result, it is evident that by transitioning the tasks into numerous threads, the operation completes at a much faster rate. In this scenario however, efficiency is sacrificed for the price of increasing speed. 14226482.162

Figure 17: Memory usage of benchmarking before snippet modification

Figure 18: Memory usage of benchmarking after snippet modification

By comparing the memory usage of Figure 17 and Figure 18, it is clearly obvious that the operation with threads uses x3 or x4 the amount of memory to complete as compared to the operation without threads. Therefore, efficiency may be compromised in this situation. Flight control system can

be considered as a hard real-time system. Therefore, high memory usage might be regarded as irrelevant if reducing latency is the number 1 concern. However, based on the tests, the average difference in completion time between the two is 2942980.221ns, which is 2.942980221ms. Due to the small difference in completion time, low memory usage may be the most efficient method as memory is not infinite and needs to be utilized efficiently. In summary, depending on the priority and hardware capabilities of the flight management system, the choice may vary.

## 4.2 Second Configuration – Data Structure

```
//linkedlist
LinkedListQueue<String> AltitudeQueue = new LinkedListQueue<String>(Arrays.asList("14675", "15745", "16834", "17924", "19014", "20104", "21194", "22284", "23374", "24464", "25554", "26644", "27734", ```

Figure 24: Configured snippet (4.3)

In Figure 24, it shows that each queue only has one element each. In summary, the third configuration imitates a situation whereas elements within the queue is constantly replaced with the latest value, drastically reducing the amount of iteration needed for the operation to acquire the desired data.

Benchmark	Mode	Cnt	Score	Error	Units
FlightControl.BM_sendActuatorFlightControl.sendInstruction	avgpt	20	9415976.569 ± 748111.914	na/op	
FlightControl.BM_sendActuatorFlightControl.sendInstruction2	avgpt	20	5267271.139 ± 221927.553	na/op	

Figure 25: Result of Optimized Code Benchmark

When iteration is reduced to one for each queue, a whopping 45% decrease in execution time, with 4348705.43ns. Overall, optimized workflow refers to the action of using alternative coding approach to acquire desired result in a shorter time frame. One of the primary examples is loops. For every iteration, the execution time increases. Thus, by reducing the number of iteration, the speed is bound to be shortened.

#### 4.4 Fourth Configuration – Redundancy

```
public class detectAltitudeSensor implements Runnable {
    AtomicInteger altitudeSensorStatus;
    AtomicInteger currentAltitude;

    public detectAltitudeSensor(AtomicInteger currentAltitude, AtomicInteger altitudeSensorStatus) {
        this.altitudeSensorStatus = altitudeSensorStatus;
        this.currentAltitude = currentAltitude;
    }

    @Override
    public void run() {
        while (true) {
            int status1 = (int) altitudeSensorStatus.get();
            try {
                Thread.sleep(1500);
            } catch (InterruptedException e) {}
            int status2 = (int) altitudeSensorStatus.get();
            if (status2 - status1 == 0) {
                System.out.println("ALTITUDE SENSOR FAILURE *DETECTED, RE-EXECUTING ALTITUDE SENSOR.4--4");
                status1 = status2;
                ScheduledThreadPoolExecutor executors = Executors.newScheduledThreadPool(1);
                executors.scheduleAtFixedRate(new Altitude_SensorBackup(altitudeSensorStatus, currentAltitude), 0, 100, TimeUnit.MILLISECONDS);
            }
        }
    }
}
```

Figure 26: Altitude\_SensorBackup Snippet

The backup mechanism works by first listening to messages sent by the altitude sensor. When a message is received, it increments an atomic integer called AltitudeSensorStatus. It also creates a thread (see Figure 26) that retrieves the current element from AltitudeSensorStatus and waits for 2500 milliseconds before retrieving it again. This is because the altitude sensor sends a message every 1500 milliseconds. If the sensor fails to send a message within 2500 milliseconds, the element within AltitudeSensorStatus will remain the same. By simple arithmetic subtraction, it can be determined whether

the altitude sensor is functioning properly or has crashed prematurely. Subsequently, when it detects that the altitude sensor thread has stopped running for 2500ms, it creates a new altitude sensor thread, to keep the simulation running.

```
Altitude Sensor -- Current altitude: 14648.00ft
Altitude Sensor -- Current altitude: 14179.00ft
Altitude Sensor -- Current altitude: 14221.00ft
Altitude Sensor -- Current altitude: 14064.00ft
ALTITUDE SENSOR FAILURE *DETECTED, RE-EXECUTING ALTITUDE SENSOR.4--4
Altitude Sensor -- Current altitude: 14006.00ft
Altitude Sensor -- Current altitude: 14156.00ft
Altitude Sensor -- Current altitude: 13893.00ft
Altitude Sensor -- Current altitude: 14127.00ft
Altitude Sensor -- Current altitude: 14548.00ft
```

Figure 27: Altitude\_SensorBackup Result

In this example (Figure 27), the altitude sensor is set to stop after 4 iteration. The Altitude\_SensorBackup has successfully picked up on that and ran the altitude sensor thread again.

This configuration is known as redundancy. By creating a backup thread, the reliability aspect of the simulation can be protected. However, as illustrated in the first configuration, the use of additional threads leads to higher usage of memory. Hence, efficiency is significantly impacted if each sensor, actuator and the flight control system need to have a backup thread each. The memory usage is bound to increase by two folds or more.

#### 5.0 Discussion

As shown in Figure 10, speed, reliability and efficiency is inter-related to performance. When one is improved, the others are compromised, such is the nature of software systems. In the result findings, when attempting to improve speed and reliability of the simulation, the memory would be significantly affected, efficiency is breached. Memory and processing power of hardware is limited, forcing a middle ground to be created between the three aspect of performance. One can't only focus on a single aspect of the performance and expects the system to work as expected. All in all, above are the developer's attempt to improve performance of the simulation, detailing the positive and negative effects

of the configurations, signifying the impact of programming designs towards performance.
